Background: Embryonic stem cells (ESc) are pluripotent cells which have been used as a model to study the mechanism that control the embryogenesis and early mammalian development in vitro. The aim of this study was to isolate and produce embryonic stem cells from late blastocyst stage embryos in mice.

Materials and Methods: Blastocyst stage embryos from pregnant NMRI mice were obtained and cultured for 24 h in DMEM medium. 4-6 days after hatching, the inner cell masses (ICM) formed colonies which were then collected mechanically and trypsinized. Several subcultures were prepared in the medium supplemented with 0.1 mM 2 Mercaptoethanol, 1000 U/ml Leukemia Inhibitory Factor (LIF) and 10% Fetal Bovine Serum (FBS). The (ESc) were recognized by alkaline phosphates histochemistry using azo-coupling method.

Results: The results demonstrated that a highly pluripotent stem cell line was derived from the blastocyst stage embryos of NMRI mice; however, the rate of colonies was as low as 10%.

Conclusion: The LIF is effective to culture and maintain the isolated ICM colonies in undifferentiated condition in the absence of feeder layer.

Key words: Embryonic stem cells, Mouse embryo, Leukemia Inhibitory Factor

Introduction

The mouse embryos at early developmental stages contain a population of cells, which are totipotent and have the ability to differentiate to somatic and germ cells (Smith 1992). Undifferentiated ICM from several mammalian blastocysts have been isolated and cultured in vitro (Pera et al., 2000; Reubinoff et al., 2000; Thomson and Marshal, 1998; Bongso et al., 1994). If these totipotent ESc are made to proliferate without differentiation could have several usages such as cell therapy, production of transgenic animals, as a model for studying the mechanism of embryo development, gene targeting and gene transfer (Odorico et al., 2001; Rathjeh et al., 1998).

The ESc have some unique properties. These cells are immortal and under influence of some factors which may differentiate into several cell lines such as endothelial, neuroepithelial, hematopoietic, and muscle cells (Smith, 1998). At first ES cell lines were obtained from rabbit embryos by Cole et al. (1965). Later, Evans and Kaufman (1981) and Martin (1981) reported their success in isolation of ESc line from mouse embryos. They cultured mouse ESc on the primary fibroblast feeder layer. Some investigators believed that

believed that co-culture of ESc with feeder layers of mitotically inactivated is not essential; however, in the presence of LIF and 2 mercaptoethanol, the ESc sustain cell survival and were undifferentiated (Smith et al., 1988; Smith and Hooper 1987).

The objective of this experimental study was to isolate the ESc from NMRI mouse blastocyst stage and compare the efficiency of LIF to inhibiting the differentiation of mouse ES.

Materials and Methods

Collection of embryo

Adult NMRI mice were maintained on a 12 h light and 12 h dark cycle. Embryos were collected by flushing the uterine horns 4 days after ovarian hyper stimulation using 10 IU injection of hMG, followed 48h later with another injection of 10 IU of hCG and natural mating. The presence of vaginal plug was examined on the morning of day one. The embryos were cultured in DMEM medium supplemented with 10% FBS for 1-2 days to allow hatching.

Embryo culture and isolation of ICM colony

The hatched blastocysts were cultured for formation of ICM colonies and their attachment to the bottom of plate. The ICM colonies were collected using the blunt heat sealed end of Pasteur pipette and transferred to a

Co₂ and 95% air. After that the cells were separated using very fine Pasteur pipette filled with DMEM medium and washing the cells several times with fresh medium. The isolated cells were transferred to 96 well dishes containing DMEM supplemented with 10% FBS and 10% newborn calf serum (NCS), 0.1 mM β mercaptoethanol and 1000 U/ml LIF. Cultures were incubated for two weeks at 37°C in water saturated atmosphere and 5% Co₂. Medium was renewed after two or three days. Each well was examined every day up

to 14 days. The colonies having typical ES morphology were subcultured. The sub culturing

method was similar to the previous procedure.

Identification of ES cells

Histochemical staining for alkaline phosphatase was carried out as described by Donovan et al, (1986). Materials for this technique were purchased from Sigma company (Sigma, St Louis, USA). Briefly, the cytoplasmic cell population was fixed with acetone formaldehyde solution (1 min), then washed with deionised water and incubated with 1mg/ml Fast Red TR salt and 40 μ l/ml Naphtol As-Mx phosphate at pH of 8.4 for 5 min. After washing and counter staining using hematoxylin solution (2 min), the samples were examined under light microscope.

Results

The summary of embryo development and formation of ICM and ES colonies are presented in Table I. 78% of embryos were hatched following incubation in DMEM for 12-14 h (Figure 1). After hatching, there were two morphologically distinct cell types, ICM colonies and trophoblast. Later, cells

were attached to the bottom of plate as a monolayer. The ICM cell colonies were small cells with a large nucleus and minimal cytoplasm (Figure 2). These cells were tightly packed and before trypsinizing were

Table I: Number of ICM and ES cell colonies from mouse blastocysts

Group	No. of Embryo	No. of Hatched Embryo (%)	No. of ICM Colony (%)	No. Of ES Colony (%)
1	115	95 (0.82)	86 (90)	8 (9)
2	100	80 (80)	71 (88)	7 (10)
3	120	92 (77)	89 (82)	9 (10)
Total	335	267 (78)	239 (89)	24 (10)

ICM = inner cell mass

ESC = embryonic stem cell

were tightly packed and before trypsinizing were difficult to recognize individual cells. The morphology of ICM colonies in the first, second and third subcultures were similar (Figure 3). However, they formed monolayer on the plate following forth subculture (Figure 4). 89% of the hatched embryos formed ICM colonies; however, only 10% of ICM colonies could produce ESC. Red staining of the cells after alkaline phosphatase histochemistry, indicated a positive enzyme reaction, which demonstrated in Figure 5.

Discussion

The main purpose of this study was to establish the isolation and production of NMRI mouse ES cells. Our results showed that the ICM colonies that were obtained from hatched NMRI mouse blastocyst could produce ES cells. After some sub culturing, the morphology of those cells were similar to the other ES cell lines, which have been obtained from another strain of mammals such as human (Bongso et al., 1994; Thomson et al., 1995; Doetschman et al., 1988). The alkaline phosphatase reaction showed that these cells became undifferentiated after some subculturing.

Our result also demonstrated that LIF in the absence of feeder layer is efficient in preventing the differentiation of ES cells. In contrast, Anderson (1992) showed an unsuccessful experiments for usage of murine and human LIF to assist isolation of ESC. Therefore, it appears that the action of LIF on ICM cells may be species as well as strain dependent.

In conclusion, the results showed that a highly pluripotent ESC can be derived from blastocyst of NMRI mice. It was also demonstrated that these cells could be differentiated into GM-CSF hematopoietic colonies (Movassagh Pour et al., 2003). Thus, this technique could be effective to produce ESC which may be used in the future reproductive studies.
